Milichiidae

338 pp

Luc DE BRUYN

Milichiidae are small to very small, greyish black or shining black flies. Lower frontoorbital bristles inclinate (sometimes reduced or absent); upper frontoorbital bristles proclinate or curved outward. Costal vein of wing broken twice: once near humeral crossvein and once just proximally to conjointment with vein R_1 ; subcosta entire, but sometimes very thin. Tibiae without preapical bristles. Ocellar triangle well developed. Proboscis often elongate; palpi large to very large and setose; vibrissae present, often very thin.

The larvae of Milichiidae are coprophagous or saprophagous in the widest sense, living in organic detritus like decaying plants, dung, kitchen refuse and birds' nests. Adult flies may be caught on carrion and dung; some species are associated with ants. Some species even attach themselves to other, predatory Diptera (e.g. Asilidae) or even to Reduviidae or spiders, by which they are transported until a prey is captured. Afterwards they sup the exudations from the wounds of the victim in company of the predator.

Data concerning the Belgian Milichiidae fauna are incorporated in Meunier (1902), Leruth (1904-05), Jacobs (1906) and Maréchal (1930). Keys are provided by Hennig (1937) and Papp (1978).
